I'm building an application that tracks my overtime and want to adjust the criteria to be as efficient as possible. The word "I" will be referred to as "the user" from now on.

00. If the stats are loaded then the application needs to update the relevant times that has not been logged or tended to by the user.

How can I make this as fair as possible while limiting any, and if possible all, exploitations.

I also want to cover each and every angle when it comes to the application to make it as user friendly, fast and convenient as

possible. Backtracks and changes should be statistically assumed to fill in the most correct information based on the time the user logged in.

I have the main page which has one clock-in and clock-out shift and when you click on clock-in or clock-out then another page open (Leftbar) which gives the option to insert two shifts in one day. I know there will be scenarios and circumstances where depending on what was inputted.

00. If the user hasn't logged am or pm on the days before the present day then insert the default working hours applied to the profile when the account was created.

00. If the user logged in, in the morning and if the time is before, after or the same as the default call time but forgot to clock-

out then use the default clock-out time set by the user.

00. If the user logs in at a pm time and forgot to clock-in then load the present time into the clock-in time.

00. If both times are inputted for the day, open the leftbar because then the best assumption will be that they want to input a second shift or change the previous week or input the next week and redo the logic by considering this as well.

I know for a fact I haven't covered every angle of the logic implementation but this program should benefit the employee more than the employer in order to retain a positive work environment for long term company growth which, now that I think about it, will benefit the employer as well.

Don't skimp on the loopholes people can use to exploit the stats.
